

Extreme-mass-ratio bursts from the Galactic Centre

Christopher P. L. Berry and Jonathan R. Gair

Institute of Astronomy, University of Cambridge, Cambridge, UK

Abstract. An extreme-mass-ratio burst (EMRB) is a gravitational wave signal emitted when a compact object passes through periaapsis on a highly eccentric orbit about a much more massive object, in our case a stellar mass object about the $4.31 \times 10^6 M_\odot$ massive black hole (MBH) in the Galactic Centre. We investigate how EMRBs could constrain the parameters of the Galaxy's MBH. EMRBs should be detectable if the periaapsis is $r_p < 65 r_g$ for a $\mu = 10 M_\odot$ orbiting object, where $r_g = GM_\bullet/c^2$ is the gravitational radius. The signal-to-noise ratio ρ scales like $\log(\rho) \simeq -2.7 \log(r_p/r_g) + \log(\mu/M_\odot) + 4.9$. For periaapses smaller than $\sim 10 r_g$, EMRBs can be informative, providing good constraints on both the MBH's mass and spin.

1. Introduction

We believe that most galactic nuclei have harboured a massive black hole (MBH) during their evolution (Lynden-Bell & Rees 1971; Rees 1984). Observations show there are correlations between the MBHs' masses and their host galaxies' properties (Kormendy & Richstone 1995; Magorrian et al. 1998; Graham et al. 2011). These suggest coeval evolution of MBH and galaxy (Peng 2007; Jahnke & Macciò 2011). Since they share a common history; one can inform us of the other.

The best opportunity to study MBHs comes from the compact object in our own galactic centre (GC), coincident with Sagittarius A* (Sgr A*). This is an MBH of mass $M_\bullet = 4.31 \times 10^6 M_\odot$ at a distance of only $R_0 = 8.33$ kpc (Gillessen et al. 2009).

According to the no-hair theorem, the MBH should be described completely by its mass M_\bullet and (dimensionless) spin a_* (Chandrasekhar 1998). The spin is related to the BH's angular momentum J by $a_* = cJ/GM_\bullet^2$. As we have a good estimate of the mass, to gain a complete description we have only to measure the spin.

An MBH accumulates mass and angular momentum through accretion (Volonteri 2010). There are several possible accretion mechanisms, each leaving its own imprint on the final spin. Measuring the spin of the MBH shall help us understand the relative importance of these processes, and gain insight into the Galaxy's past.

An exciting means of inferring information about the MBH is through gravitational waves (GWs) emitted when stellar mass compact objects (COs) pass close by (Sathyaprakash & Schutz 2009). A space-borne detector can detect GWs in the frequency range of interest for these encounters (Danzmann & Rüdiger 2003; Amaro-Seoane et al. 2012). Much work has already been done on the waveforms generated when COs inspiral towards an MBH (Glampedakis 2005; Barack 2009). The initial orbits may be highly elliptical and a burst of radiation is emitted during each close encounter. These are extreme mass-ratio bursts (EMRBs; Rubbo, Holley-Bockelmann, &

Finn 2006). These orbit can evolve, becoming more circular, and then emitting continuously in the detector frequency range. These signals are extreme mass-ratio inspirals (EMRIs; Amaro-Seoane et al. 2007).

We investigate high eccentricity orbits, which can result as the consequence of two-body encounters. We make the simplifying assumption that all these orbits are marginally bound, or parabolic, since highly eccentric orbits appear almost indistinguishable from an appropriate parabolic orbit.¹ The event rate for detectable EMRBs has been estimated as 1 yr^{-1} (Hopman, Freitag, & Larson 2007). Even if only a single burst is detected, this should still give an unparalleled probe of the structure of space-time of the GC. What can be inferred depends upon the orbit, which is investigate here.

We use the classic *Laser Interferometer Space Antenna (LISA)* design for this work. It is hoped that any future detector shall have comparable sensitivity to *LISA*, and that studies using this design shall be a sensible benchmark.

2. Numerical kludge waveforms

For given angular momenta, and initial starting position, we can calculate the geodesic trajectory in a Kerr background. The orbiting body is assumed to follow this track exactly; we ignore evolution due to the radiation, which should be negligible for EMRBs. From this trajectory we calculate the waveform using a semirelativistic approximation (Ruffini & Sasaki 1981): we assume the particle moves along a geodesic, but radiates as in flat spacetime. This is known as a numerical kludge (NK), and well approximates results computed by more accurate methods (Babak et al. 2007). The use of the geodesic ensures the correct frequency components, but the flat-space wave generation means they do not have precisely the correct amplitudes.

NK approximations aim to encapsulate the main characteristics of a waveform by using the exact particle trajectory (ignoring inaccuracies from radiative effects and from the particle’s self-force), whilst saving on computational time by using approximate waveform generation.

We build an equivalent flat-space trajectory from the Kerr geodesic. This is done by identifying the standard Boyer-Lindquist coordinates (Boyer & Lindquist 1967) with a set of flat-space coordinates. We use spherical polars so $\{r_{\text{BL}}, \theta_{\text{BL}}, \phi_{\text{BL}}\} \rightarrow \{r_{\text{sph}}, \theta_{\text{sph}}, \phi_{\text{sph}}\}$ (Gair, Kennefick, & Larson 2005). Using oblate-spheroidal coordinates yields similar results.

With a flat-space trajectory, we may apply a flat-space wave generation formula. We use the quadrupole-octupole formula (Bekenstein 1973; Press 1977; Yunes et al. 2008).

3. Waveforms and detectability

3.1. Model parameters

The waveform depends on the properties of the MBH; the CO and its orbit, and the detector. We assume the position of the detector is known, and the MBH is coincident with the radio source of Sgr A*, which is within $20r_g$ of the MBH (Reid et al. 2003;

¹Here “parabolic” and “eccentricity” refer to the energy of the geodesic and not to its geometric shape.

Doeleman et al. 2008). We use the J2000.0 coordinates, which are determined to high accuracy (Reid et al. 1999; Yusef-Zadeh et al. 1999). The parameters left to infer are: (1) The MBH's mass M_\bullet . This is well constrained by the observation of stellar orbits about Sgr A* (Ghez et al. 2008; Gillessen et al. 2009), the best estimate is $M_\bullet = (4.31 \pm 0.36) \times 10^6 M_\odot$. (2) The spin parameter a_* . (3,4) The orientation angles for the black hole spin Θ_K and Φ_K . (5) The ratio of the GC distance and the compact object mass $\zeta = R_0/\mu$. This scales the amplitude of the waveform. Bursts do not undergo orbital evolution, hence we cannot break the degeneracy in ζ . The distance is constrained by stellar orbits $R_0 = 8.33 \pm 0.35$ kpc (Gillessen et al. 2009). (6, 7) The angular momentum of the CO. We use the angular momentum at infinity L_∞ and the orbital inclination, ι . (8–10) Coordinates specifying the trajectory. We use the angular phases at periaapse, ϕ_p and θ_p , as well as the time of periaapse t_p .

3.2. Signal-to-noise ratio

The detectability of a burst depends upon its SNR ρ . The amplitude of the waveform is proportional to the CO mass; we work in terms of a mass-normalised SNR $\hat{\rho} = (\mu/M_\odot)^{-1}\rho$. We considered a range of orbits. The spin of the MBH and the orbital inclination were randomly chosen, and the periaapse distance was set so that the distribution would be uniform in log-space (down to the inner-most orbit). For each set of the extrinsic parameters, the periaapse positions, orientation of the MBH, and orbital position of the detector were varied: we used five combinations of these intrinsic parameters (each drawn from a separate uniform distribution), taking the mean of $\ln \rho$ for each set.

The correlation between the periaapse radius and SNR is shown in fig. 1. The shape

Figure 1. Mass-normalised SNR as a function of periaapse radius. The points are the values averaging over each set of intrinsic parameters. The best fit line is $\log(\hat{\rho}) = -2.69 \log(r_p/r_g) + 4.88$ for orbits with $r_p > 13.0 r_g$.

of the curve is predominately determined by the noise curve. The change in the trend reflects the transition from approximately power law behaviour into the bucket of the noise curve. We fit a fiducial power law to orbits with a characteristic frequency of

Figure 2. Distribution widths as functions of periaapse r_p . Filled circles are used for converged runs; open circles for unconverged runs. The dotted line is the current uncertainty for M_\bullet ; the dashed line the standard deviation for an uninformative prior, and the solid line the total prior range.

$f_* = \sqrt{GM_\bullet/r_p} < 1 \times 10^{-3}$ Hz, to avoid spilling into the bucket. Changing the cut-off within a plausible region alters the fit coefficients by ~ 0.1 .

Setting a detection threshold of $\rho = 10$, a $1M_\odot$ ($10M_\odot$) CO should be detectable if $r_p < 27r_g$ ($65r_g$).

4. Parameter estimation & results

Having detected a GW signal, we are interested in what we can learn about the source. We performed Markov chain Monte Carlo (MCMC) simulations to characterise the posterior probability distribution. Waveforms were computed for a range of orbits. In each case the MBH has the standard mass and position. The CO was chosen to be $10M_\odot$, as the most promising candidates for EMRBs would be stellar mass black holes: they are massive and hence produce higher SNR bursts, they are more likely to be on close orbits as a consequence of mass segregation, and they cannot be tidally disrupted. Orbits were chosen with periaapses uniformly distributed in logarithmic space (to the inner-most orbit). The other parameters were chosen randomly from appropriate uniform distributions.

It is possible to place good constraints from the closest orbits, although there is significant correlation between parameters. The standard deviation σ of the recovered posteriors are shown in fig. 2 for the mass and spin. Filled circles are used for MCMC runs that have converged. Open circles are for those yet to converge; widths should be accurate to a factor of a few. These results do not incorporate any priors (save to keep them within realistic ranges). Therefore, the resulting distributions characterise what we could learn from EMRB's alone. By the time a space-borne GW detector finally flies, we may well have much better constraints for some parameters.

4.1. Scientific potential

The current uncertainty in the mass is $\sigma_{M_\bullet} = 0.36 \times 10^6 M_\odot$ ($\sim 8\%$). It appears that orbits of a $\mu = 10M_\odot$ CO with periaapses $r_p \lesssim 13r_g$ should be able to match this. Accuracy of 1% is possible if $r_p \lesssim 8r_g$.

The spin is less well constrained. To obtain an uncertainty for the magnitude of 0.1, comparable to that achieved in X-ray measurements of active galactic nuclei, the periaapsis needs to be $r_p \lesssim 11r_g$. As the spin encodes information of the merger and accretion history, this could illuminate the MBH's formation.

We have no *a priori* knowledge about the CO or its orbit, so anything we learn would be new. However, this is not particularly useful information, unless we observe multiple bursts, and can start to build up statistics for the dynamics of the GC. Using current observations for the distance to the GC, which could be further improved by the mass measurement from the EMRB, it is possible to infer a value for the mass μ from ζ . This could inform us of the nature of the object (BH, NS or WD) and be a useful

consistency check. A small value of ζ , indicating a massive CO would be unambiguous evidence for the existence of a stellar mass black hole.
